

FIRST LOOK AT THE AGL MEASUREMENTS

Jorge Casaus
CIEMAT

Goal

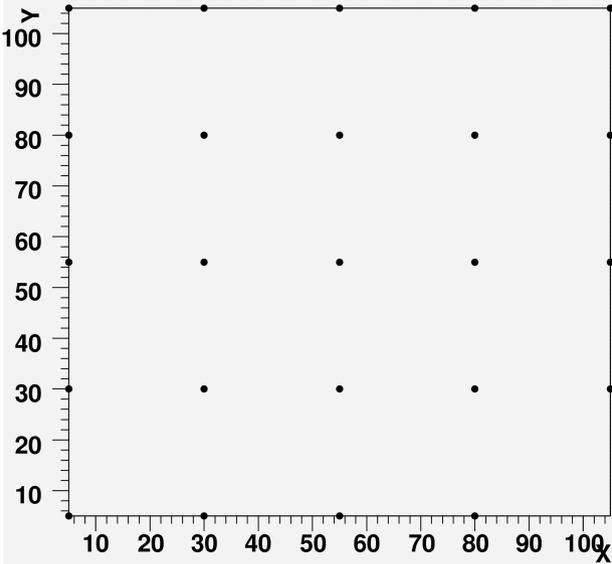

- Analyse the metrology and optical measurements performed at LPSC to conclude either
 - ✓ The need of dedicated real detector package (simulation & reconstruction)
 - ✓ An estimate of the safety margin wrt the “ideal” detector settings
- Assert the completeness of the measurements and their correct translation into the RICH Sim/Rec software

Sample

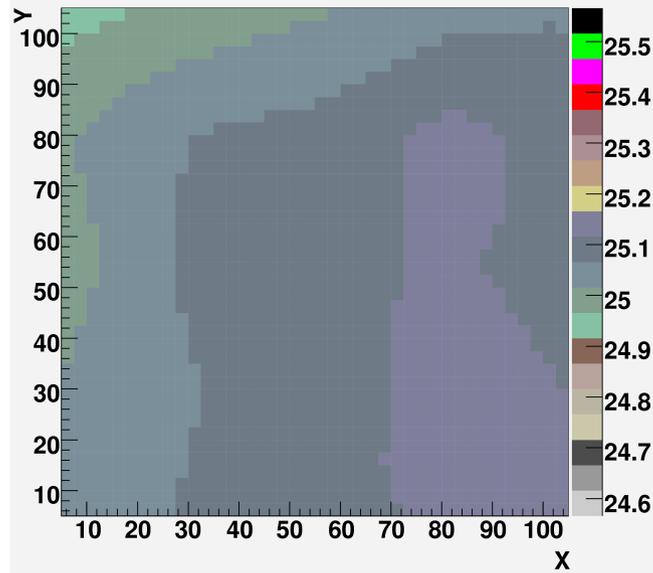

- Consisting in the measurements provided by Mariane on 51 tiles corresponding to the first batches received at Grenoble
- 2 types of measurements:
 - ✓ Metrology Scan (Thickness) (~25 meas. 25 mm pitch)
 - ✓ Optical Scan (Refractive Index) (~400 meas. 4.7 mm pitch)
- 44 tiles selected with “good” Metrology & Optical measurements
 - ✓ 32 (T1) + 4 (T2) + 4 (T3) + 4 (T5)

Thickness & Index Mapping

STRATEGY :

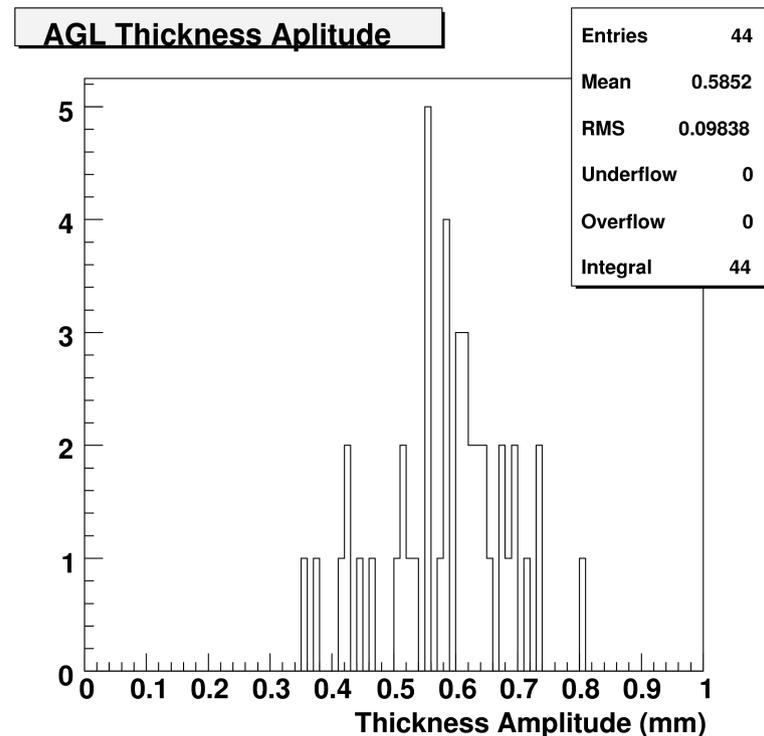

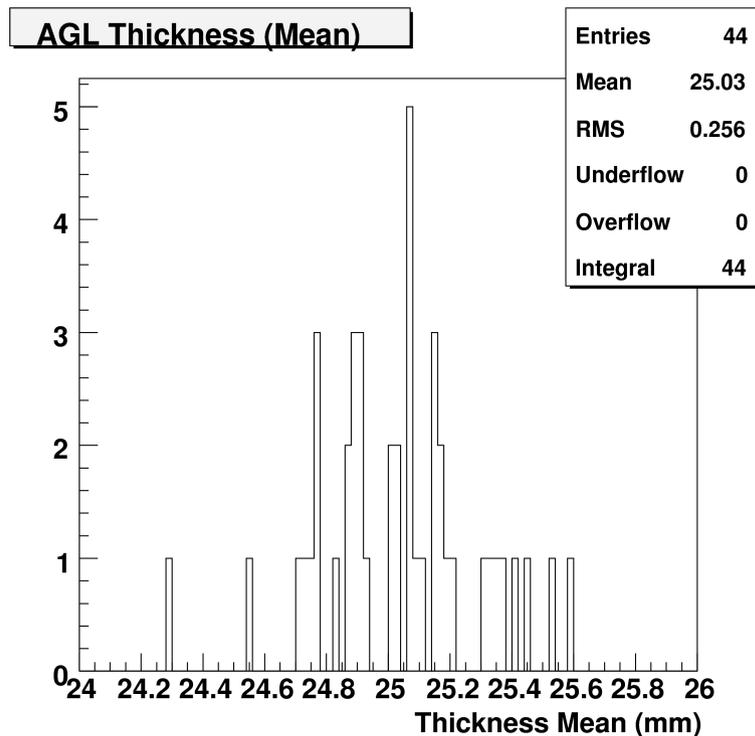

- Sample points uniform distributed in the tile surface
- Use ROOT embeded interpolation (based on Delaunay Triangles) to map the AGL thickness/index
- Compute relevant quantities on interpolated data (Mean/RMS/gradients/...)

CAVEAT EMPTOR :

- Coarse pitch – 25(4.7) mm - can limit the validity of the interpolation
- No extrapolation assumed: Tile edges not properly mapped

Thickness Mapping

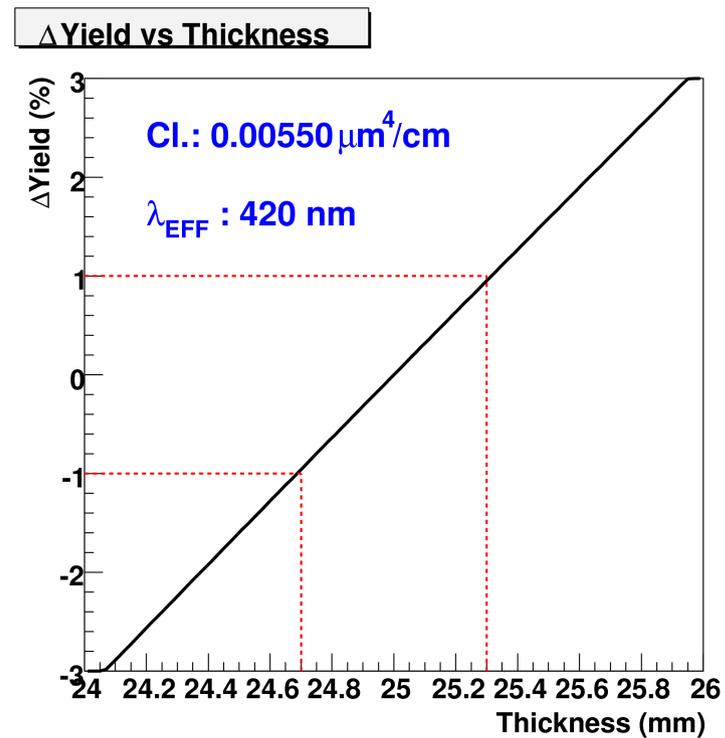

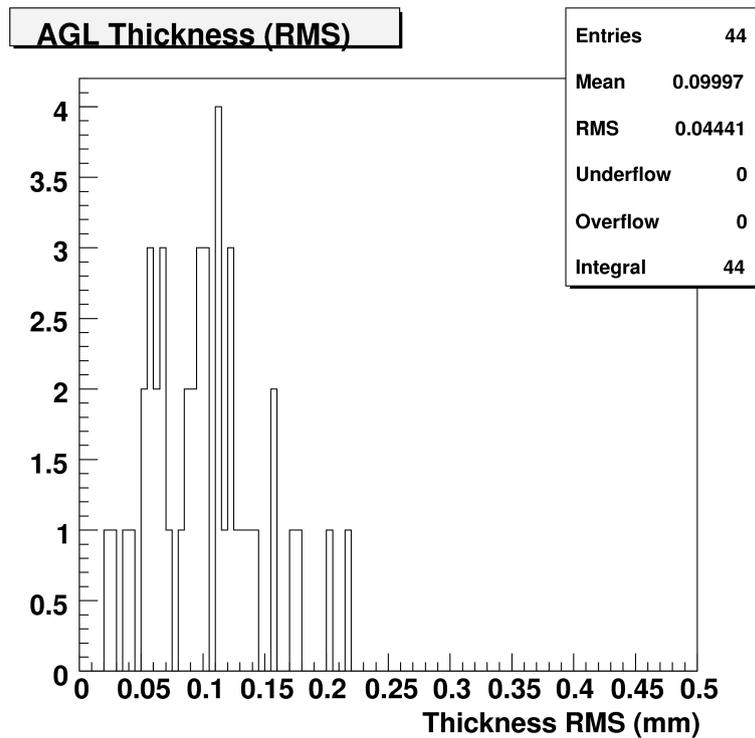

- The average mean-thickness of the AGL tiles is 25.0 mm with an RMS of 1% (for a total amplitude of $\pm 3\%$)
- The average thickness-amplitude (ThickMax-ThickMin) is 0.6 mm with a maximum below 0.8 mm

Thickness Mapping

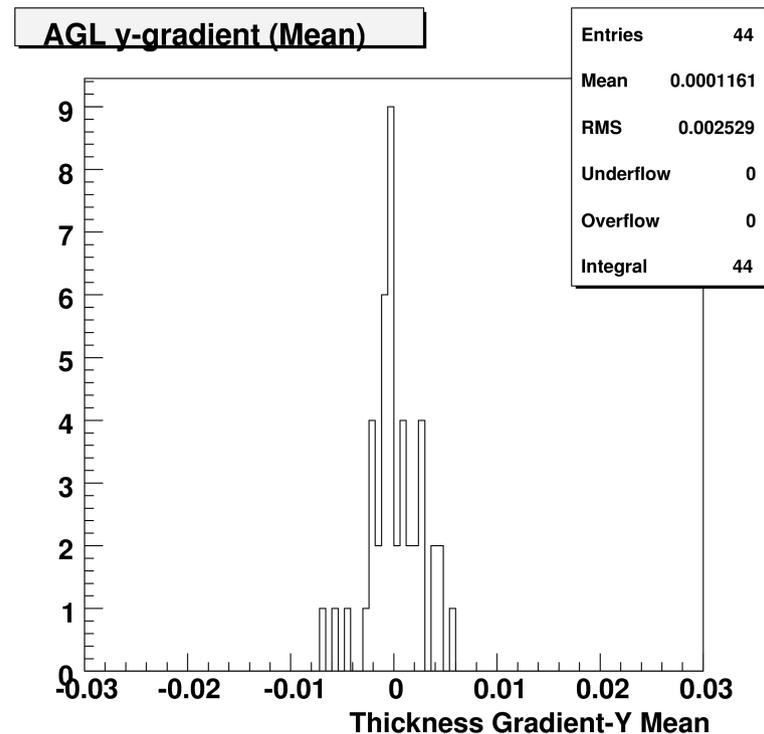

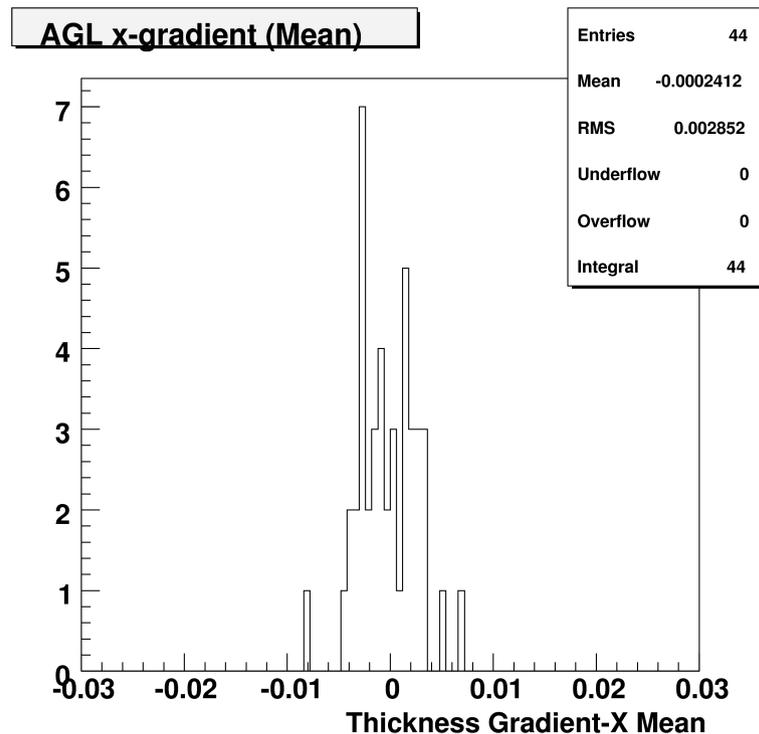

- The average RMS-thickness of the AGL tiles is 0.1 mm with a maximum below 0.25 mm

The photon yield under control (<1%) with a single parameter per tile

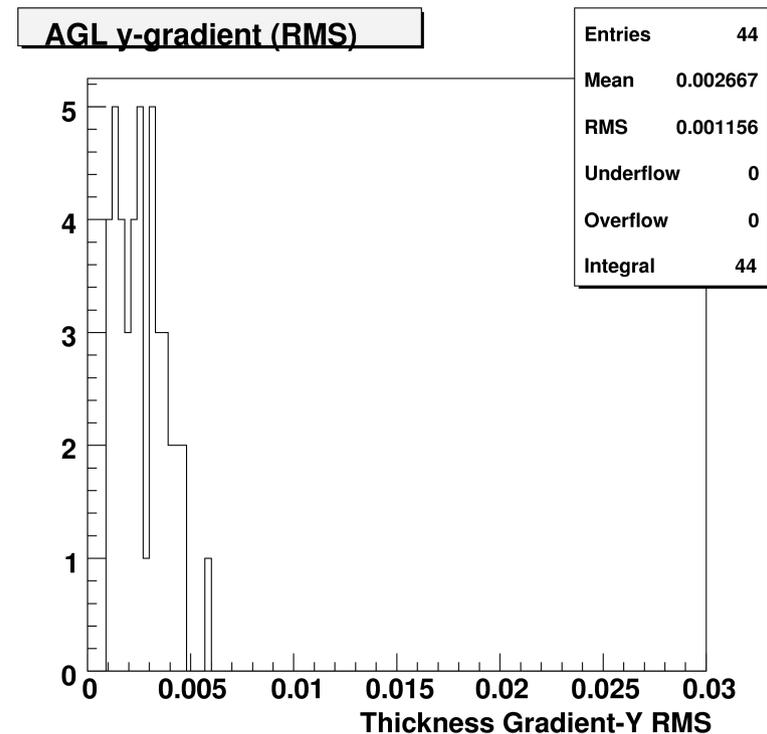

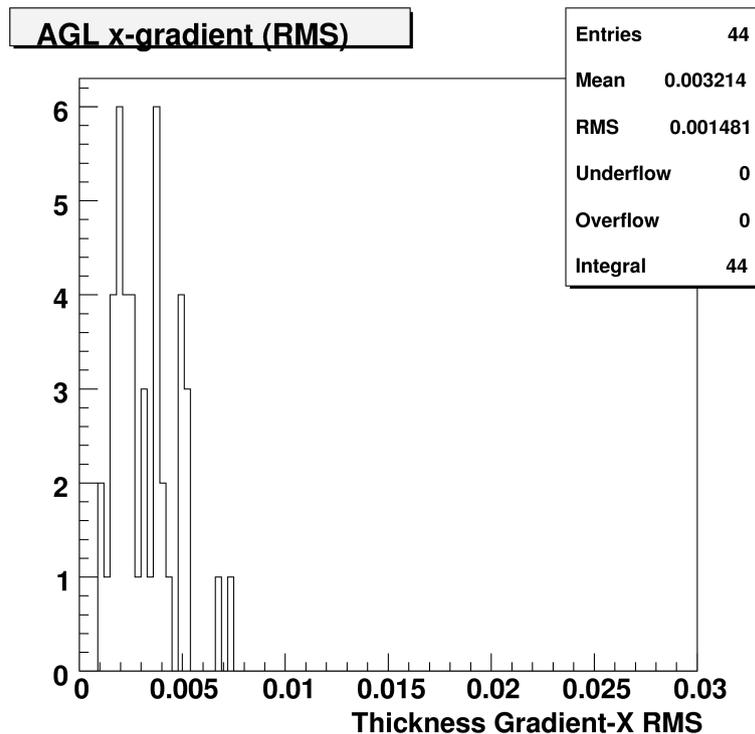

Thickness Mapping

- The surface gradients (dz/dx , dz/dy) could affect the velocity reconstruction through an anomalous refraction at the radiator exit
- The mean gradients indicate an effective slope of the tile
- The effect on the reconstructed velocity small due to left/right compensations on the Cerenkov cone (to be checked with MC)

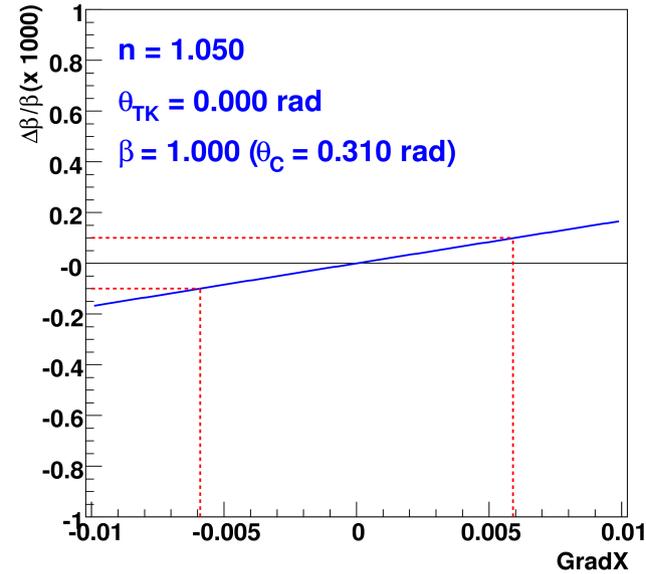

Thickness Mapping

- The widths of the distributions of thickness gradients determine the size of an extra smearing of the β resolution ($\Delta\beta/\beta \sim (n-1)/n * \sigma$)
- The average RMS is 0.003 both for gradX and gradY
- We can study the maximum acceptable value for different configurations not to spoil the high-Z resolution ($\sim 0.1\%$)

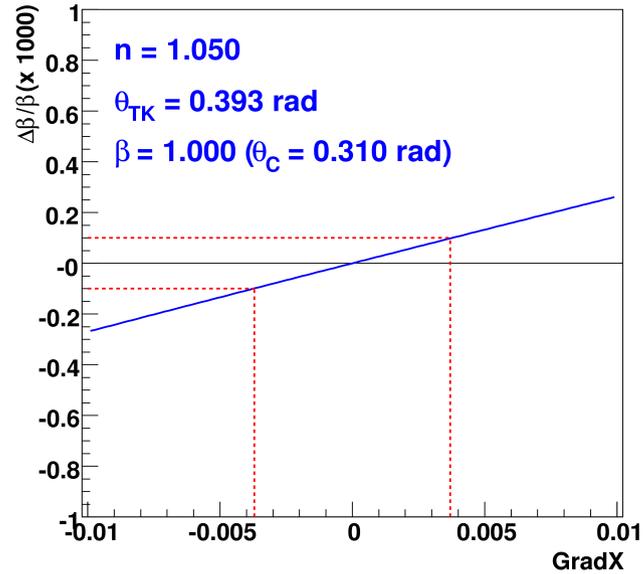

$\Delta\beta/\beta$ vs GradX

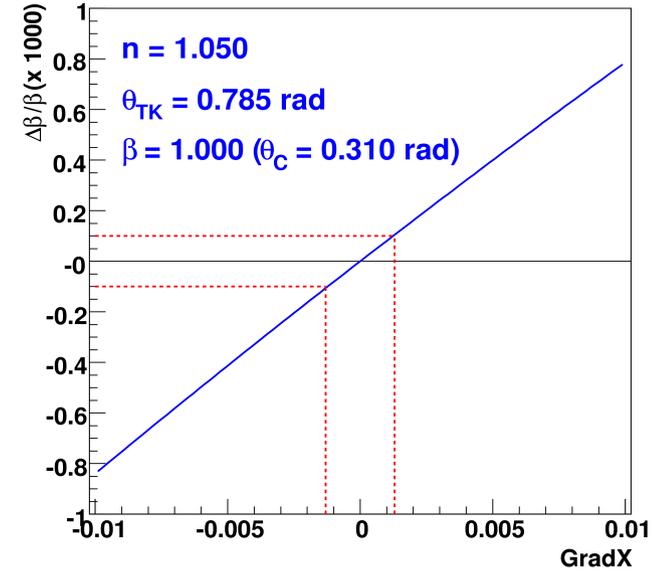

$\Delta\beta/\beta$ (x 1000) vs GradX

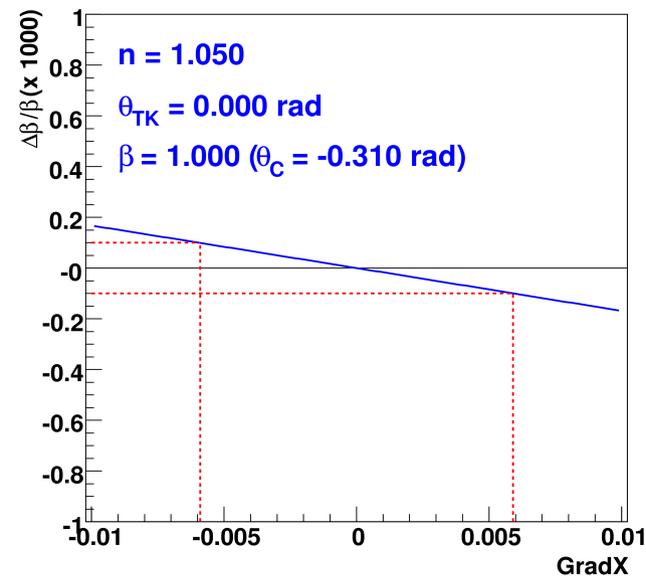

$\Delta\beta/\beta$ (x 1000) vs GradX

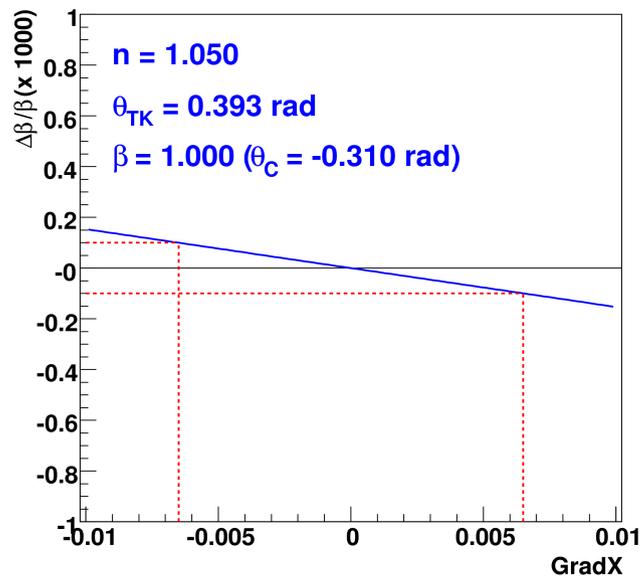

$\Delta\beta/\beta$ (x 1000) vs GradX

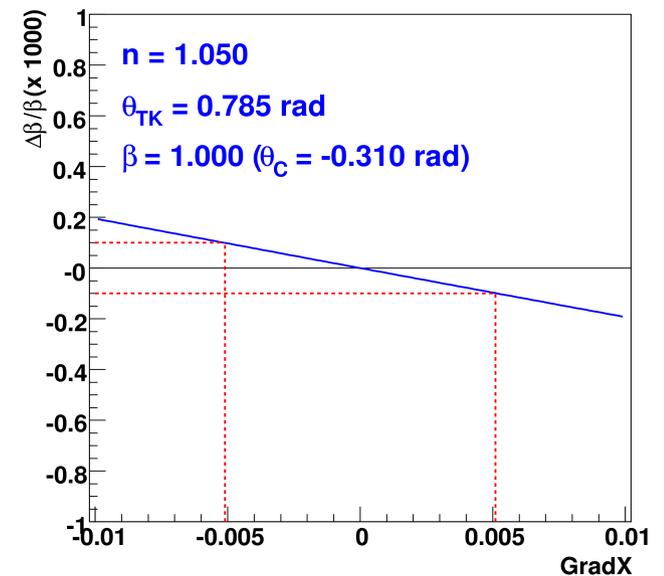

$\Delta\beta/\beta$ (x 1000) vs GradX

$\Delta\beta/\beta$ (x 1000) vs GradX

$\Delta\beta/\beta$ (x 1000) vs GradX

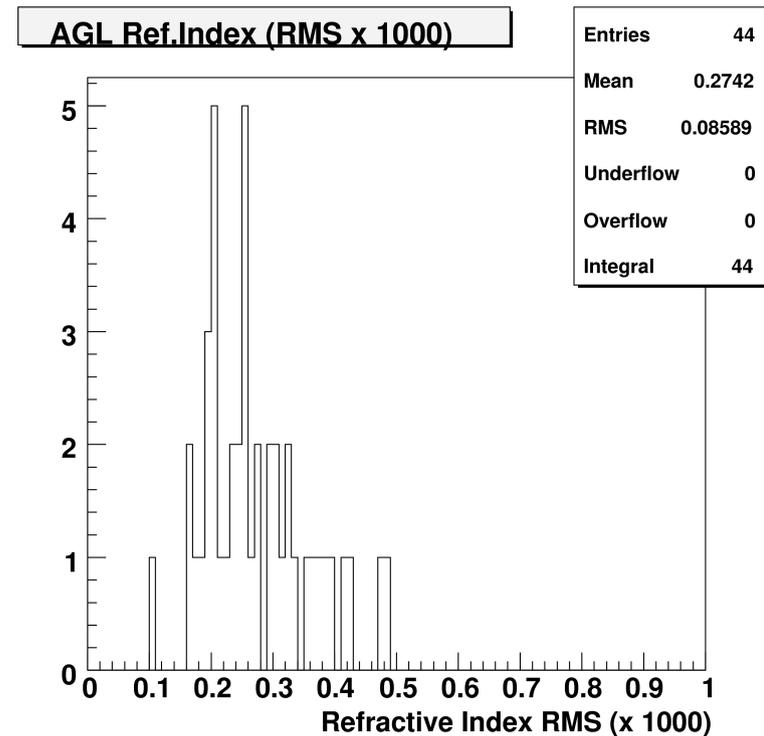

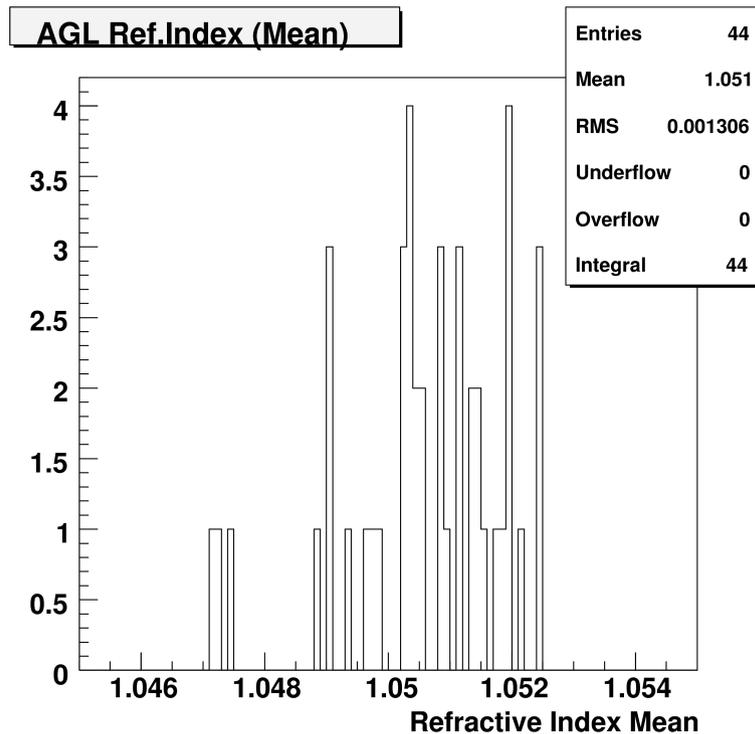

Thickness Mapping

- Only extreme configurations (e.g. $\theta_{TK} = \pi/4$, $\beta=1$ & $\alpha=\theta_{TK} + \theta_C$) could compromise the high-Z resolution for the measured thickness gradients (mean RMS = 0.003)
- Though only negligible effects are expected, this **should be confirmed with the simulation**

Index Mapping

- The average mean-index of the AGL tiles is 1.051 with an RMS of 1.2‰ (for a total amplitude of $\pm 3\text{‰}$)
- The average index-RMS is 0.3‰

The refractive index must be modeled to avoid the ‰ tile-to-tile variation and the intra-tile variations above the 0.1‰

Next Steps

- Use MC simulation with simple radiator geometry to confirm the open points:
 - Mean gradient (i.e. inclination) compensation
 - RMS gradient negligible
- Try simple modeling to avoid tile-to-tile and intra-tail refractive index variations
- DB/Sim/Rec updates
- Include recent measurements
